Abstract

Angiosarcomas are a rare group of tumours which have poor prognosis and limited treatment options. The development of new therapies has been hampered by a lack of good preclinical models. Here we describe the development of an autochthonous mouse model of angiosarcoma driven by loss of p53 in VE-cadherin expressing endothelial cells. Using Cdh5-Cre to drive recombination in adult endothelial cells, mice developed angiosarcomas with 100% penetrance upon homozygous deletion of Trp53 with a median lifespan of 325 days. In contrast, expression of the R172H mutant p53 resulted in formation of thymic lymphomas with a more rapid onset (median lifespan 151 days). We also used Pdgfrb-Cre expressing mice which targets predominantly pericytes, as these have been reported as the cell of origin for a number of soft tissue sarcomas. Pdgfrb-Cre also results in low levels of recombination in venous blood endothelial cells in multiple tissues during development. Upon deletion of Trp53 in Pdgfrb-Cre, Trp53^{fl/fl} mice 65% developed lymphomas and 21% developed pleomorphic undifferentiated soft tissue sarcomas. None developed angiosarcomas. In contrast, 75% of Pdgfrb-Cre, Trp53^{R172H/R172H} mice developed angiosarcomas with 60% of these mice also developing lymphomas. The median lifespan of the Pdgfrb-Cre, Trp53^{R172H/R172H} mice was 151 days. Re-implantation of angiosarcoma tumour fragments from Cdh5-Cre, Trp53^{fl/fl} mice provided a more consistent and rapid model of angiosarcoma than the two spontaneous models. The ability to passage tumour fragments through the mouse provides a novel model which is amenable to preclinical studies and will help the development of potential new therapies for angiosarcoma.

Key Words: angiosarcoma, p53, genetically engineered mouse model
Introduction

Angiosarcomas are rare but aggressive endothelial cell tumours. Most arise spontaneously but they also develop following ionizing radiation and chronic lymphedema. They have a high risk of local recurrence and metastasis with limited treatment options such that the overall 5-year survival is around 35% [1]. They typically express endothelial markers such as CD31 and vascular endothelial growth factor (VEGF) and for this reason there is interest in the use of anti-angiogenic therapies for their treatment. Data from a number of clinical trials show promising activity of the VEGF-A monoclonal antibody bevacizumab and broad spectrum, small molecule tyrosine kinase inhibitors that target VEGF receptors [1]. However, the underlying pathways driving the pathogenesis of angiosarcoma are not well defined and together with the urgent need for effective therapies we set out to develop an autochthonous mouse model of angiosarcoma that could aid preclinical drug development efforts.

Mutations in TP53 have been reported in human angiosarcomas with incidences of between 4 and 52% reported in different studies [2-8]. In addition, mice with germline deletion of Trp53 which are pre-disposed to development of lymphoma develop angiosarcomas in significant numbers [9,10]. The predominance and rapid development of lymphoma in these models precludes their usefulness as models of angiosarcoma. Attempts have therefore been made to overcome this by use of tissue specific Cre-Lox recombination of conditional alleles and alymphocytic mice [11,12].

There is increasing evidence that mesenchymal stem cells (MSCs) may be the cell of origin of a number of different sarcoma sub-types [13-18]. Coupled with the evidence that pericytes have been proposed as the identity of MSCs in normal tissues [19,20] and some sarcomas share
features of pericytes such as expression of NG2 and CD146 [21,22], we set out to address whether Pdgfrb-Cre and Cdh5-CreERT2 mice could be utilized to generate a model of angiosarcoma. Pdgfrb-Cre mice express Cre recombinase under the control of a fragment of the gene encoding platelet-derived growth factor receptor-β (PDGFR-β). This drives Cre mediated recombination in pericytes in a number of tissues [23,24] and low levels of recombination in venous blood endothelial cells in multiple tissues during development [25,26]. This allows us to target loss of p53 function to the pericyte lineage while also potentially targeting endothelial cell lineages. Cdh5-CreERT2 mice express Cre recombinase under the inducible control of the vascular endothelial cadherin (VE-cadherin; Cdh5) promoter in adult mice to drive expression in endothelial cells [27].

It is widely accepted that mutant forms of p53 can exert dominant negative or gain-of-function effects that contribute to tumour development beyond that seen following loss of the wild type p53 protein alone [28,29]. Individuals with Li-Fraumeni syndrome carry inherited mutations in TP53 and are predisposed to tumour development including sarcomas. In mouse models of Li-Fraumeni syndrome expression of Trp53R172H, which corresponds to the TP53R175H hot spot mutation in human tumours, mice develop predominantly lymphomas but a small percentage also develop angiosarcomas [30,31]. We therefore generated mice in which Trp53R172H was expressed under the control of Pdgfrb-Cre and Cdh5-CreERT2 in addition to those carrying a floxed Trp53 allele.
Materials and Methods

Animals

Mice expressing Cre under the control of the Pdgfrb promoter (Pdgfrb-Cre) [23] or in the inducible control of the Cdh5 promotor (Cdh5-CreER<sup>T2</sup>) [27], were crossed to mice expressing either a mutant p53R172H [31] or floxed p53 allele [32] to give experimental cohorts on a mixed background segregating for C57BL/6J and S129 genomes. The mutant p53 allele is preceded by a STOP cassette, flanked by LoxP sites, such that upon activation of Cre recombinase the STOP cassette is excised and the mutant p53R172H expressed, while in the floxed p53 mice activation of Cre deletes exons 2-10 resulting in a loss of p53. Pdgfrb-Cre and Cdh5-CreER<sup>T2</sup> mice were also crossed with Ai14 (Rosa-CAG-LSL-tdTomato-WPRE) mice [33], obtained from the Jackson Laboratory, to allow endogenous reporting in Pdgfrb and Cdh5 expressing cells. Genotyping was carried out by Transnetyx (Cordova, TN). Cdh5-CreER<sup>T2</sup> mice were treated with tamoxifen (Sigma) (100 mg/kg, i.p.) for 5 days at 6 weeks of age. Mice were monitored twice weekly and sacrificed when cutaneous tumours had reached a maximum size of 1.5 cm or became sickly as defined by UK Home Office guidelines. Following sacrifice macroscopically identified tumours and major organs were removed and fixed in 10% neutral buffered formalin. In some instances, fresh samples were taken for generation of cell lines or tumour fragments taken for re-implantation. Animal studies and procedures were approved by the University of Edinburgh Ethical review committee (Application #PL01-16) and conducted in accordance with United Kingdom Home Office regulations.
**Histology and immunohistochemistry**

Formalin fixed tissues were routinely processed into paraffin wax blocks and sections cut for H&E staining and immunohistochemistry. Immunohistochemistry was carried out as previously described [34]. Primary antibodies used were CD31 at 1:800 (Abcam, ab28364), ERG (Dako, IR659), p53 at 1:2000 (Leica BioSystems, NCL-L-p53-CM5p), PDGFRβ at 1:100 (CST, 3169S), and VE-cadherin at 1:4000 (Abcam, ab33168).

**Immunofluorescence**

Shaved dorsal skin was mounted on 3 mm blotting paper and placed in 4% methanol-free formaldehyde (Thermo-Fisher Scientific, 28906) at 4°C for one hour. The skin was then washed with PBS and transferred to 18% sucrose overnight for cryoprotection prior to embedding in OCT embedding matrix (Cellpath, KMA-0100-00A) and frozen on dry ice. 7 μm cryotome sections were dried at room temperature in the dark for 30 minutes and washed in PBS containing 0.05% Tween 20 (Sigma Aldrich, P2287). To image endogenous tdTomato fluorescence, sections were incubated with 1 μM DAPI for 10 minutes, washed twice with PBS, and mounted with Prolong Gold (Thermo-Fisher Scientific, P36930). For indirect immunofluorescence staining, sections were incubated with blocking buffer (PBS containing 5% goat serum (Vector, S-1000) and 0.3% Triton X100 (Sigma Aldrich, T8787) for 30 minutes, then incubated with primary antibodies PDGFRβ (1:25, Abcam Ab32570) or CD31 (1:50, BD Pharmingen 550274) for 2 hours. Sections were then washed twice and incubated for 30 minutes with Alexafluor 488 conjugated secondary antibodies (Molecular Probes Inc - goat anti-rabbit 488 (A11034) or goat anti-rat 488 (A11006), washed twice, incubated with DAPI and mounted as described above. Images were obtained on a Zeiss LSM780 confocal microscope.
Cell culture

Tumours from $Pdgfrb$-Cre, $p53^{R172H/R172H}$ mice were freshly processed by rinsing in PBS and then mincing to ~1 mm$^3$ pieces using two scalpels. After transferring to a 15 ml Falcon tube containing 10 mL digestion media (maintenance medium omitting fetal bovine serum (FBS) and including 300 U/mL collagenase I (Worthington) and 100 U/mL hyaluronidase (Fisher), cells were subjected to shaking incubation at 37°C for 18 hours. After pelleting at 1300 rpm for 5 minutes cells were resuspended in 2 mL maintenance media (DMEM/Ham’s F12 (Sigma), 10% FBS (Gibco), amphotericin (Gibco) and penicillin-streptomycin (Sigma)) before being transferred to a six well plate. Cells were left undisturbed for 5-7 days in a humidified incubator at 37°C with 5% CO$_2$ before refreshing media and moving on to flasks when confluent. Tumours from $Cdh5$-CreER$^{T2}$, $Trp53^{lofl}$ mice were manually minced using scalpels and left undisturbed for 5-7 days before transferring to flasks when confluent. Cells were maintained in Ham’s F-12K Medium (Gibco), 10% FBS (Gibco), amphotericin B (Gibco), penicillin-streptomycin (Sigma), 0.1 mg/mL heparin (Sigma) plus 20 µg/mL endothelial cell growth supplement (Sigma, E2759) and checked routinely for mycoplasma infection.

Western analysis

SDS denatured protein samples made from RIPA lysates were run on 4-15% precast polyacrylamide gels (Biorad) in Tris/Glycine/SDS running buffer (Biorad) and transferred onto nitrocellulose using the Trans-Blot® Turbo System (Biorad). After blocking the membrane in 5% BSA in PBS, anti-p53 antibody (VectorLabs, VP-P955) was added at 1:50 overnight at 4°C on a shaking platform. The membrane was washed in TBS-T thrice before being incubated with an HRP conjugated anti-rabbit secondary antibody (CST, #7074) at 1:1000). Washes were repeated and then the membrane visualized on a ChemiDoc (BioRad) using ECL western blotting substrate (Pierce).
Gene expression profiling

RNA prepared from angiosarcomas that developed in the Pdgfrb-Cre, p53^{R172H/R172H} and Cd5-CreER^{T2}, Trp53^{fl/fl} mice was analyzed using the NanoString PanCancer Pathways panel (represents 750 cancer associated genes) on the NanoString nCounter DX platform as per the manufacturer’s instructions. For comparison Cd5 positive liver endothelial cells were isolated from Ai14;Cd5-CreER^{T2} mice 3 weeks following tamoxifen treatment [35]. A Cd5 (tdTomato) positive population of endothelial cells was collected using a BD FACS&Aria II. Following standard nCounter normalisation differentially expressed genes were identified using Student’s t-tests (p<0.05) between the angiosarcomas derived from the Pdgfrb-Cre, p53^{R172H/R172H} and Cd5-CreER^{T2}, Trp53^{fl/fl} mice and relative to the normal endothelial cells. Hierarchical cluster analysis was performed with the Cluster and Treeview programs [36]. Gene set enrichment analysis [37] was performed using the Phenotest R package. Gene ontology analysis was performed using the PANTHER classification system [38].

Sub-cutaneous tumour growth

Cell lines and tumour fragments derived from the mouse angiosarcomas were injected into both flanks of 6-8 week old female CD-1 nude mice (Charles River) and tumour growth measured twice weekly using calipers. Tumour volumes were calculated in Excel using the formula \( v = \frac{4}{3}\pi r^3 \). Animals were sacrificed when tumours reached the maximum size allowed and collected and fixed in 10% neutral buffered formalin.
RESULTS

Tumour development in Pdgfrb-Cre, Trp53$^{R172H/R172H}$ and Pdgfrb-Cre, Trp53$^{0/0}$ mice

Experimental cohorts consisted of mice expressing either one (Pdgfrb-Cre, Trp53$^{R172H/+}$) (n=16) or two (Pdgfrb-Cre, Trp53$^{R172H/R172H}$) (n=28) mutant Trp53$^{R172H}$ alleles or loss of both Trp53 alleles (Pdgfrb-Cre, Trp53$^{0/0}$) (n=14). The median lifespan of the Pdgfrb-Cre, Trp53$^{R172H/R172H}$ mice was 93 days compared to >365 days for the Pdgfrb-Cre, Trp53$^{R172H/+}$ mice and 189.5 days for the Pdgfrb-Cre, Trp53$^{0/0}$ mice (Figure 1A). The deaths of all Pdgfrb-Cre, Trp53$^{R172H/R172H}$ mice were due to tumour formation in contrast to the Pdgfrb-Cre, Trp53$^{R172H/+}$ cohort where only 2/16 mice were culled due to tumour formation. In the Pdgfrb-Cre, Trp53$^{0/0}$ cohort 12/14 mice were culled due to tumour formation. Mice that were asymptomatic at 1 year of age were culled.

Autopsy findings and tumour histology

In the Pdgfrb-Cre, Trp53$^{R172H/R172H}$ cohort 75% (n=21/28) of the mice developed angiosarcomas. Of these 21 mice, 9 demonstrated only angiosarcomas whilst in the other 12 mice lymphomas were also identified. The remaining Pdgfrb-Cre, Trp53$^{R172H/R172H}$ mice developed either lymphomas (n=5/28) or teratomas (n=2/28) (Figure 1B). Thus, the predominant tumour type was angiosarcoma with most mice developing multiple angiosarcomas in a number of different organs (Table 1) (Figure 1B: median 3, range 1-6 tumours). No angiosarcomas were seen in the Pdgfrb-Cre, Trp53$^{R172H/+}$ mice. The 2 Pdgfrb-Cre, Trp53$^{R172H/+}$ mice culled due to tumour formation had developed lymphomas. At autopsy, following culling of the asymptomatic Pdgfrb-Cre, Trp53$^{R172H/+}$ mice at 1 year, 3 were found
to have developed lymphomas and 1 adenocarcinoma in the lung. The remainder showed no gross or histological abnormality (Figure 1C). Within the Pdgfrb-Cre, Trp53^{fl/fl} mice 9 developed lymphomas and 3 undifferentiated sarcomas upon histological examination, while the remaining 2 had no detectable tumour upon sacrifice (Figure 1D).

Characterization of angiosarcomas in Pdgfrb-Cre, Trp53^{R172H/R172H} mice
The morphological appearances of the angiosarcomas were similar within and between mice. The tumours consisted of lobules of pleomorphic cells showing varying degrees of vascular formation typical of high-grade angiosarcomas (Figure 2A, B). Immunohistochemistry supported the morphological assessment with the tumour cells expressing CD31 and ERG (Figure 2C, D). There was no expression of CD34 by the tumour cells (not shown). The tumours also showed strong expression of p53 (Figure 2E) in keeping with the stabilization of mutant p53 that is often seen in human tumours expressing mutant p53. PDGFR-β was expressed by stromal cells within the tumour masses but not reliably by the angiosarcomatous cells (Figure 2F).

Development of undifferentiated sarcomas in Pdgfrb-Cre, Trp53^{fl/fl} mice
Three of the 14 (21%) Pdgfrb-Cre, Trp53^{fl/fl} mice developed tumours with the morphological features of high-grade spindle cell and pleomorphic undifferentiated soft tissue sarcoma (Figure S1A). Immunohistochemistry showed no expression of p53 confirming the homozygous deletion of p53 in the Pdgfrb-Cre, Trp53^{fl/fl} mice (Figure S1B) and strong expression of PDGFR-β by the tumour cells (Figure S1C). Less than 10% of the cells expressed SMA in 2 of the cases whilst the other was completely negative for SMA. None of the tumour cells expressed CD31 (Figure S1D) or ERG (not shown).
PDGFR-β Cre recombination does not occur in adult CD31 endothelial cells

As the angiosarcomas that developed expressed CD31 but did not express PDGFR-β we asked whether there was any Cre mediated recombination in CD31 positive endothelial cells in adult mice. Using Ai14 reporter mice (single-fluorescent reporter mice that express tdTomato after Cre-mediated recombination)[33] we found that Pdgfrb-Cre induced highly efficient recombination in mouse skin (Figure 3A), a tissue where a number of angiosarcomas arose in the Pdgfrb-Cre, Trp53<sup>R172H/R172H</sup> mice. To evaluate the specificity of recombination, we stained skin from Ai14;Pdgfrb-Cre mice for PDGFR-β and confirmed appropriate reporter expression by Pdgfrb-Cre (Figure 3B). Staining of Ai14;Pdgfrb-Cre mice skin for CD31 expression showed that recombination did not target adult endothelial cells and in some cases PDGFR-β expressing cells were seen surrounding small CD31 positive endothelial cells (Figure 3C). This suggests that the angiosarcomas have arisen either from endothelial cell lineages that transiently express PDGFR-β during development [25,26] or from other PDGFR-β expressing pericyte lineages. Interestingly the undifferentiated sarcomas that developed in the Pdgfrb-Cre, Trp53<sup>fl/fl</sup> mice had retained expression of PDGFR-β suggesting a different cell of origin.

Tumour development in Cdh5-Cre<sup>ER<sup>T2</sup>, Trp53<sup>R172H/R172H</sup> and Cdh5-Cre<sup>ER<sup>T2</sup>, Trp53<sup>fl/fl</sup> mice</sup>

To determine whether we could promote more efficient generation of angiosarcomas we directly induced expression of mutant p53 or loss of p53 in adult endothelial cells using Cdh5-Cre<sup>ER<sup>T2</sup> mice where Cre recombinase is driven by Cdh5, which encodes the endothelial specific VE-cadherin. Using Ai14;Cdh5-Cre<sup>ER<sup>T2</sup> reporter mice we found that Cdh5-Cre induced recombination in CD31 positive endothelial cells (Figure S2). Experimental cohorts consisted of mice expressing either one (Cdh5-Cre<sup>ER<sup>T2, Trp53<sup>R172H/+</sup></sup>) (n=15) or two (Cdh5-
CreER\textsuperscript{T2}, Trp53\textsuperscript{R172H/R172H} (n=8) mutant Trp53\textsuperscript{R172H} alleles or loss of one (Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/+}) (n=9) or both Trp53 alleles (Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{0/0}) (n=13). A control cohort of Cdh5-CreER\textsuperscript{T2} mice were also treated with tamoxifen (n=9). The median lifespan of Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{R172H/R172H} mice was 151 days (range 109 - 198) (Figure 4A). In the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{R172H/+} cohort 2/16 mice developed tumours and all others were asymptomatic mice and sacrificed at 1 year (Figure 4A, B). The median lifespan of Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/+} mice was 325 days (range 224 - 407) (Figure 4A). All were culled due to tumour formation.

All Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/+} and Cdh5-CreER\textsuperscript{T2} mice were asymptomatic at 12 months of age and culled with no evidence of tumour formation upon autopsy.

**Autopsy findings and tumour histology**

In the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{R172H/R172H} cohort 7/8 mice developed thymic lymphomas, with evidence of thymic hyperplasia in the remaining mouse, but none developed angiosarcomas (Figure 4B). Two of the mice that developed lymphomas also developed additional tumours: one an undifferentiated sarcoma and the other a hepatocellular carcinoma. In addition, one of the Cdh5-CreER\textsuperscript{T2} mice showed evidence of thymic hyperplasia with all the others showing no evidence of tumour formation upon autopsy (Figure 4B). In the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{R172H/+} mice two developed tumours: one a thymic lymphoma and the other an angiosarcoma (Figure 4B). At autopsy, following culling of the asymptomatic Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{R172H/+} mice at 1 year, the remainder showed no gross or histological abnormality. Thus, the predominant tumour type driven by Trp53\textsuperscript{R172H} in the Cdh5-CreER\textsuperscript{T2} mice was lymphoma in contrast to the angiosarcomas that developed in the Pdgfrb-Cre, Trp53\textsuperscript{R172H/R172H} mice. Within the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{0/0} cohort all mice developed angiosarcomas (13/13), many with multiple tumours which developed in a range of anatomical locations (Table 2) (Figure 4B). The Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/+} mice had no detectable tumour upon sacrifice. When we looked at the
latency of the angiosarcomas and the lymphomas in all experimental mice we found that the lymphomas developed more rapidly than the angiosarcomas with a median survival of 163 days (range 109 - 198) days and 325 days (range 224 - 407) respectively (Figure 4C).

**Characterization of angiosarcomas in Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/fl} mice**

Many of the tumours were similar to those seen in the Pdgfrb-Cre, Trp53\textsuperscript{R172H/R172H} mice comprising lobules of pleomorphic cells showing varying degrees of vascular formation (Figure 5A). However, many of the tumours showed extensive hemorrhage and necrosis. In some tumours a cavernous / telangiectatic pattern was evident with enlarged blood-filled spaces being lined by atypical endothelial cells. Immunohistochemistry supported the morphological assessment with the tumour cells expressing ERG, CD31 and VE-cadherin but not PDGFR\(\alpha\) (Figure 5). 12/13 tumours that developed in the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/fl} mice, did not express p53 (Figure 5F). The reason for p53 expression in the remaining angiosarcoma is not known.

**Comparison of gene expression profiles of Pdgfrb-Cre, Trp53\textsuperscript{R172H/R172H} and Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/fl} tumours**

To understand the differences between the angiosarcomas that developed in the Pdgfrb-Cre, Trp53\textsuperscript{R172H/R172H} and the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/fl} mice we carried out gene expression analysis using the NanoString PanCancer Pathways panel. Tumour type specific gene expression profiles were determined by unsupervised hierarchical clustering with both tumour types also being significantly more different than normal Cdh5 derived endothelial cells (Figure 6A). Gene ontology analysis of the genes that were significantly differentially expressed between the two different angiosarcoma subsets showed that pathways linked to p53 and angiogenesis, including FGF and VEGF signalling pathways were over represented (Figure 6B). This
indicates that the gain of function Trp53R172H mutant drives expression of a different set of genes to those seen in the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{0/0} mice, to initiate angiosarcoma development.

To determine whether the differentially expressed genes gene changes seen in the mouse angiosarcomas reflect changes seen in human angiosarcomas we carried out gene set enrichment analysis of the differentially expressed genes in the mouse angiosarcomas compared to normal endothelial cells and compared this with published human data from a set of human angiosarcomas and normal endothelial cells (GSE4415: [39]). This showed a significant enrichment of genes associated with human angiosarcomas in the mouse tumours compared to those expressed in the normal endothelial cells (Figure 6C), indicating that the mouse angiosarcomas represent a sub-population of human angiosarcomas. Interestingly, analysis of genes associated with endothelial cell function showed that a number were significantly increased in angiosarcomas in both the human and mouse datasets (VEGFC, EPHA2), while others were differentially regulated in the human and mouse angiosarcomas (VEGF, VEGFB, KDR, MYC) (Figure 6D).

**Generation of cell lines and transplantation model**

We generated cell lines from 4 angiosarcomas that developed in the Pdgfrb-Cre, Trp53\textsuperscript{R172H/R172H} and mice. As with the spontaneous tumours, the cell lines all expressed p53 (Figure 7A) and genotyping showed that each cell line was homozygous for the R172H allele. Upon re-implantation of the cell lines into the flanks of mice two of the lines from the Pdgfrb-Cre, Trp53\textsuperscript{R172H/R172H} mice developed tumours, with morphological features of undifferentiated pleomorphic sarcomas (Figure 7Bi). Neither the generated cell lines nor the tumours retained expression of CD31 (Figure 7Bii). We also generated cell lines from four angiosarcomas that developed in the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{0/0} mice. Genotyping confirmed that each cell line was
homozygous for the floxed Trp53 allele. However, none of the cell lines formed tumours when injected into the flanks of recipient mice. In an attempt to overcome the loss of endothelial markers upon culture of the angiosarcomas we implanted tumour fragments from three spontaneous angiosarcomas that developed in the Cdh5-CreER<sup>T2</sup>, Trp53<sup>0/0</sup> mice. All formed tumours and histological examination confirmed that these were angiosarcomas expressing both CD31 and ERG (Figure 7C, D). Furthermore, secondary implantation of frozen tumour fragments resulted in successful outgrowth of angiosarcomas in recipient wild type mice (Figure 7C, D).

**Discussion**

We have generated two mouse models of angiosarcoma driven by deregulation of p53. We used the Pdgfrb-Cre mouse that is known to target both pericytes and endothelial cells during development. This resulted in 75% of Pdgfrb-Cre, Trp53<sup>R172H/R172H</sup> mice developing angiosarcomas, which is higher than the 62% reported when Tie2-Cre mice were crossed to Trp53 floxed mice [11]. In this model p53 is deleted in both endothelium and the hematopoietic lineages. Interestingly we saw no angiosarcomas in the Pdgfrb-Cre, p53<sup>0/0</sup> mice suggesting that the Trp53<sup>R172H</sup> mutant is exerting a gain-of-function activity that is required for angiosarcoma development when Pdgfrb cells are targeted. The development of angiosarcomas in a small percentage of mice in a model of Li-Fraumeni syndrome that expresses Trp53<sup>R172H</sup> supports the specific involvement of mutant p53 in the development of angiosarcoma [30,31]. Analysis of Pdgfrb-Cre mice has shown that recombination occurs in a number of cell types during development including endothelial and mural cells [25,26] so it is not possible to define the cell of origin in the angiosarcomas that developed in the Pdgfrb-Cre, Trp53<sup>R172H/R172H</sup> mice.
The cell of origin of sarcomas remains unclear although mounting evidence suggests that they are derived from mesenchymal cells [40]. NG2/CSPG4 is a cell surface proteoglycan expressed by pericytes, which are mesenchymal cells that surround blood vessels [41]. A recent study has shown that targeting p53 loss in adult mice using NG2/CSPG4 driven Cre recombination leads to the formation of bone and soft tissue sarcomas supporting the mesenchymal origin of these tumours [17]. In this study only one angiosarcoma developed indicating that they can arise from mesenchymal precursors but that the efficiency is much lower than that of other sarcoma types such as osteosarcomas and undifferentiated pleomorphic sarcomas that were the most frequent tumour types seen. Interestingly we found that loss of p53 in the Pdgfrb-Cre mice gave rise to undifferentiated sarcomas that expressed PDGFR-β, albeit with a reduced efficiency and increased latency compared to that observed by Sato and colleagues. These differences may reflect differences in the efficiency of recombination in the Pdgfrb-Cre and Ng2/Cspg4-Cre mice or may be due to distinct pericyte subpopulations that are marked by PDGFR-β and NG2 during development [42]. In the future, use of a conditional Pdgfrb-iCreER\textsuperscript{T2} mouse [43] that allows specific deletion of Trp53 in the adult where Pdgfrb expression is restricted to pericytes, will allow further evaluation of the role of distinct mesenchymal cell lineages to the development of different sarcoma sub-types.

To address whether direct targeting of adult endothelial cells would result in the development of angiosarcomas with higher efficiency we used the Cdh5-CreER\textsuperscript{T2} mouse. Surprisingly all Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{R172H/R172H} mice developed lymphomas. Studies in Cdh5-CreER\textsuperscript{T2} mice have reported recombination of a small (0.3%) subpopulation of bone marrow cells that are hematopoietic in nature [44]. Combined with the propensity of mutant p53 to drive lymphomagenesis this appears sufficient to drive development of lymphomas in the Cdh5-
CreERT2, Trp53R172H/R172H mice. However, all of the Cdh5-CreERT2, Trp53fl/fl mice developed angiosarcomas with no lymphomas detected. The enrichment of genes associated with p53 in the differentially expressed genes between the tumours that develop in the two models indicates that, as expected, the gain of function Trp53R172H mutant drives expression of a different set of genes to those seen in the Cdh5-CreERT2, Trp53fl/fl mice, to initiate angiosarcoma development. Other mouse models targeting specific endothelial cell populations have also been reported. mTORC1 activation in endothelial cells following conditional deletion of its upstream inhibitor Tsc1 resulted in 100% of mice developing hepatic hemangiomas, and around 80% developing cutaneous lymphangiosarcomas [45]. This is in contrast to the aggressive angiosarcomas that developed upon direct targeting of Trp53 in endothelial cell lineages in the Cdh5-CreERT2, Trp53fl/fl mice. mTORC1 pathway activation has also been reported in human angiosarcomas [45,46] and has been linked to Myc-mediated transcriptional regulation of VEGF [45]; increased expression of both Myc and Vegfa in the angiosarcomas from the Cdh5-CreERT2, Trp53fl/fl mice suggest that a similar autocrine stimulation loop may be present in these tumours, although the involvement of mTORC signaling in these tumours is not known. Combined loss of Trp53, Pten and Ptpn12 also leads to the development of aggressive vascular lesions which was associated with both mTORC and MEK pathway activation suggesting that mTORC activation alone is not sufficient to drive aggressive angiosarcoma development [46]. In this study loss of Trp53 alone did not result in the development of angiosarcomas. However, the tumours arose from more restricted recombination in a sub-set of endothelial cells. Taken together with the distinctive spectrum of tumours seen upon deletion of Tsc1 this suggests that targeting distinct populations of endothelial cells in mice in combination with differential pathway activation impacts on the type and site of vascular tumour development.
Increased Myc expression downstream of the forkhead boxO (FoxO) pathway has been linked to endothelial cell proliferation and angiosarcoma development [48,49]. Interestingly, conditional triple knock-out of FOXO1, 3, 4 in mice results in development of thymic lymphomas and vascular lesions, predominantly haemangiomas, in a number of tissues with only 9% progressing to angiosarcomas, although there is no reported role for Myc in this model [38]. This is in contrast to the Cdh5-CreER\textsuperscript{T2}, Trp53\textsuperscript{fl/fl} mice where angiosarcomas arise predominantly in soft tissues as the vascular lesions that develop in the FOXO triple knock out mice are predominantly benign and arise in relation to the uterus and a number of other tissues [38]. FOXOs and p53 share many common target genes and may act in a cooperative manner in order to regulate gene transcription [50,51]. It will be interesting to establish whether the deregulation of such pathways is required for driving the transition from benign to malignant disease in the mouse models.

Angiosarcomas in humans may be divided into several clinical groups. The majority of cases, around 50%, are cutaneous, breast parenchymal angiosarcomas account for around 14% of angiosarcomas, soft tissue 11%, heart 7% and bone 4% with a range of other sites accounting for the remainder [47]. Little is known of the factors that predispose to angiosarcoma development in the clinical setting and it may be that angiosarcomas constitute a range of interrelated clinical diseases with common endothelial features but different phenotypes and aetiologies. Comparison of gene expression profiles between the two mouse models and human angiosarcomas showed significant enrichment of angiosarcoma associated genes in the two models suggesting that the mouse models do represent some of the phenotypes present in the human disease. Use of these and other mouse models will help to unravel some of the targetable pathways in angiosarcoma.
Although genetically engineered models are used in preclinical studies, the long latency of tumour formation in the \textit{Cdh5-CreER}\textsuperscript{T2}, \textit{Trp53}\textsuperscript{fl/fl} mice (median lifespan 325 days) and the development of multiple tumours, would make therapeutic efficacy studies costly and challenging. Knock-out of p53 in alymphocytic \textit{Rag2}\textsuperscript{−/−};\textit{Il2rg}\textsuperscript{−/−} mice leads to a high frequency of angiosarcomas (over 65\%) with only sporadic formation of lymphomas. With a mean latency of 18 weeks this provides an alternative model that would be more amenable to therapeutic studies \cite{12}. However, the lack of immune cell populations in these mice restricts their use for assessing immune modulators which are showing promise in sarcoma. A recent report has shown that use of a lentiviral vector-based system to introduce oncogenic \textit{Hras}\textsuperscript{G12V} in combination with loss of \textit{Cdkn2a} via intravenous injection into immune competent mice resulted in the formation of angiosarcomas. These develop very rapidly and in multiple sites which is most likely influenced by the intravenous route of injection \cite{40}. This provides a useful model for preclinical studies but the rapid development of multiple tumours will make these studies challenging.

To overcome these issues, we generated cell lines from angiosarcomas that developed in the \textit{Pdgfrb-Cre}, \textit{Trp53}\textsuperscript{R172H/R172H} and \textit{Cdh5-CreER}\textsuperscript{T2}, \textit{Trp53}\textsuperscript{fl/fl} mice in an attempt to generate syngeneic mouse models of angiosarcoma. However, as has been reported previously \cite{11}, endothelial makers were rapidly lost when the tumours were established in culture, even when grown with endothelial cell specific supplements. In contrast, direct implantation of tumour fragments allowed us to establish angiosarcomas which could be frozen and passaged serially through wild type recipient mice. This had the benefit of reducing the latency of tumour formation while also restricting the number of tumours per mouse. Furthermore, the sub-
cutaneous localization of the tumours allowed easy monitoring of tumour growth. We have used this transplantation approach previously to model HER2 breast cancer and have demonstrated its utility in determining drug efficacy and establishing models of drug resistance [34].

Taken together our data indicate that deleting p53 in endothelial cells in the adult mouse is the most effective way to generate angiosarcomas. This resulted in 100% penetrance with no formation of lymphomas. The development of lymphomas in the Cdh5-CreER\textsuperscript{T2}, \textit{Trp53}\textsuperscript{R172H/R172H} mice supports a strong selection for angiosarcoma formation following loss of p53 in contrast to expression of the gain-of-function mutant p53. This is supported by angiosarcoma formation in mice in which loss of \textit{Trp53} is combined with loss of \textit{Ptpn12} and \textit{Pten} [41]. The further establishment of a transplantation model of angiosarcoma provides a novel approach for testing potential new therapeutics in this disease setting.
