Abstract

Higher health literacy is associated with higher cognitive function and better health. Despite its wide use in medical research, no study has investigated the genetic contributions to health literacy. Using 5783 English Longitudinal Study of Ageing (ELSA) participants (mean age = 65.49, SD = 9.55) who had genotyping data and had completed a health literacy test at wave 2 (2004–2005), we carried out a genome-wide association study (GWAS) of health literacy. We estimated the proportion of variance in health literacy explained by all common single nucleotide polymorphisms (SNPs). Polygenic profile scores were calculated using summary statistics from GWAS of 21 cognitive and health measures. Logistic regression was used to test whether polygenic scores for cognitive and health-related traits were associated with having adequate, compared to limited, health literacy. No SNPs achieved genome-wide significance for association with health literacy. The proportion of variance in health literacy accounted for by common SNPs was 8.5% (SE = 7.2%). Greater odds of having adequate health literacy were associated with a 1 standard deviation higher polygenic score for general cognitive ability [OR = 1.34, 95% CI (1.26, 1.42)], verbal-numerical reasoning [OR = 1.29, 95% CI (1.21, 1.36)], and years of schooling [OR = 1.29, 95% CI (1.21, 1.36)]. Reduced odds of having adequate health literacy were associated with higher polygenic profiles for poorer self-rated health [OR = 0.92, 95% CI (0.87, 0.98)] and schizophrenia [OR = 0.91, 95% CI (0.85, 0.96)]. The well-documented associations between health literacy, cognitive function and health may partly be due to shared genetic etiology. Larger studies are required to obtain accurate estimates of SNP-based heritability and to discover specific health literacy-associated genetic variants.

Keywords: Health literacy; genome-wide association study; genetic; intelligence; education; health

Health literacy is ‘the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions’ (Institute of Medicine, 2004). This capacity is thought to be important for navigating all aspects of health care, including the ability to seek out and act on appropriate health information and self-manage health conditions (Baker, 2006; Institute of Medicine, 2004). Tests of functional health literacy have been used to investigate the association between health literacy and health. Individuals with lower health literacy have been found to be less likely to take part in health-promoting behaviors (von Wagner et al., 2007). Lower health literacy is associated with poorer overall health status (Berkman et al., 2011), lower self-reported physical and mental health (von Wagner et al., 2007; Wolf et al., 2005) and greater self-reported depressive symptoms (Gazmararian et al., 2000). One study (Wolf et al., 2005) found that individuals with inadequate health literacy were 48% more likely to report a diagnosis of diabetes and 69% more likely to report having heart failure, compared to those with adequate health literacy, after adjusting for sociodemographic variables and health behaviors. Using prospective studies, lower health literacy predicted incident dementia (Kaup et al., 2014; Yu et al., 2017) and risk of dying (Baker et al., 2007; Berkman et al., 2011; Bostock & Steptoe, 2012).

Compared with those of health literacy, similar associations with health have been found for cognitive function. Individuals with higher cognitive function tend to participate more in health-promoting behaviors (Mons et al., 2013; Richards et al., 2003; Taylor et al., 2003; Wraw et al., 2018). Vascular risk factors, including diabetes and hypertension, have been associated with poorer cognitive function and greater cognitive decline (Knopman et al., 2009; Möttus et al., 2013; Pavlik et al., 2005; Singh-Manoux & Marmot, 2005). Cognitive function, measured early in life, has been found to predict later life physical functioning and health status (Wraw et al., 2015), psychological distress (Gale et al., 2009), psychiatric illness (Batty et al., 2005; Dickson et al., 2012; Gale et al., 2008; Scult et al., 2017; Zammit et al., 2004), dementia (McGurn et al., 2008), and death (Batty et al., 2007; Calvin et al., 2011, 2017; Christensen et al., 2016).

Performance on tests of health literacy and cognitive function are moderately to highly correlated (Boyle et al., 2013; Möttus et al., 2014; Murray et al., 2011; Reeve & Basalik, 2014). Murray et al. (2011) found that the correlations between general cognitive ability and three tests of health literacy, tested in older adulthood, ranged from .35 to .53 (p < .001). Given these correlations, researchers have sought to determine whether the relationship between health literacy and health remained when also accounting for cognitive function. Cognitive function has been consistently found to
attenuate the size of the association between health literacy and health; however, whereas some studies have found that health literacy no longer predicted better health when controlling for cognitive function (Fawns-Ritchie et al., 2018b; Möttus et al., 2014; O’Connor et al., 2015; Serper et al., 2014), others have found that a small but significant association remained between higher health literacy scores and better health when also controlling for cognitive function (Baker et al., 2008; Bostock & Steptoe, 2012; Fawns-Ritchie et al., 2018a; Möttus et al., 2014; Yu et al., 2017).

Whereas there is a wealth of evidence reporting a relationship between health literacy, cognitive function and health, it is less well understood why these associations are found. One possibility is that they share genetic influences. Cognitive function is substantially heritable (Deary et al., 2019; Haworth et al., 2010; Plomin & Deary, 2015). With increasing sample sizes, the specific genetic variants associated with cognitive function are being identified (Davies et al., 2018; Savage et al., 2018). One study (Hagenaars et al., 2016) sought to explore the shared genetic architecture between cognitive function and health, using two complementary genetic techniques: linkage disequilibrium (LD) score regression (Bulik-Sullivan et al., 2015) and polygenic profile scoring (Purcell et al., 2009). The first technique involves calculating the genetic correlations between two traits of interest using summary results from previous genome-wide association studies (GWAS). The second technique uses summary GWAS data for a specific trait (e.g., type 2 diabetes) and tests whether the genetic variants found to be associated with this trait are also associated with the same (e.g., type 2 diabetes) or a different (e.g., cognitive function) phenotype in an independent sample. Using these techniques, Hagenaars et al. (2016) found substantial shared genetic influences between cognitive function and physical and mental health. Negative genetic correlations were found between a test of verbal-numerical reasoning and Alzheimer’s disease ($r_s = -0.39$, $p = .002$), and schizophrenia ($r_s = -0.30$, $p = 3.5 \times 10^{-11}$), among others. Polygenic profiles for various mental and physical health–related variables were associated with performance on tests of cognitive function, including coronary artery disease, Alzheimer’s disease and schizophrenia. The shared genetic architecture between cognitive function and health has been subsequently replicated using larger samples (Davies et al., 2018).

Summaries are available regarding the advances made in understanding the genetic architecture of cognitive function and its overlap with physical and mental health (Deary et al., 2019; Hill, Harris et al., 2019). However, to the best of our knowledge, no one has investigated the genetic contributions to people’s differences in health literacy. The aim of the present study was to explore the genetic contributions to health literacy and its overlap with cognitive function and health. Using data from the English Longitudinal Study of Ageing (ELSA), a sample of English adults aged 50 years and older, the present study conducted a GWAS of health literacy, estimated its single nucleotide polymorphism (SNP)-based heritability, and used polygenic profile scoring to examine the genetic overlap between health literacy and cognitive function, and health literacy and various health–related traits.

Materials and Methods

Participants

This study used data from ELSA (https://www.elsa-project.ac.uk/), a cohort study designed to be representative of English adults aged 50 years and older (Steptoe et al., 2013). The original sample (wave 1) was recruited in 2002–2003 and consisted of 11,391 participants. Participants have been followed up every 2 years and the sample has been refreshed at subsequent waves to ensure the sample’s representativeness. Interviews took place via computer-assisted personal interviews and self-completion questionnaires in the participants’ own homes. The topics assessed included health, financial and social circumstances. A nurse visit was carried out every second wave to measure biomarkers. Blood samples collected during the nurse visit have been used to genotype ELSA participants. More information on the ELSA sampling procedures are reported elsewhere (Steptoe et al., 2013). For the present study, a subsample of participants was used who completed the health literacy test at wave 2 (2004–2005) and who had genome-wide genotyping data ($n = 5783$).

Procedure

Health literacy. Health literacy was measured using a four-item reading and comprehension test. This test was designed to mimic written materials, such as drug labels, that would be encountered in a health-care setting. A piece of paper containing instructions for an over-the-counter packet of medicine was given to participants. Participants were asked four questions about the information on the medicine packet (e.g., “What is the maximum number of days you may take this medication?”). One point was awarded for each correct answer. As has been done in other studies (Gale et al., 2015; Kobayashi et al., 2014), participants were categorized as having adequate (4/4 questions correct) or limited (<4 correct) health literacy.

Genotyping and quality control. A total of 7597 ELSA participants who had provided blood samples were genotyped in two batches (batch 1, $n = 5652$; batch 2, $n = 1945$) by UCL Genomics using the Illumina Omni 2.5-8 chip. Quality control procedures were performed by UCL Genomics and by the present authors. This included removal of SNPs based on call rate, minor allele frequency (MAF) and deviation from Hardy–Weinberg equilibrium. Individuals were removed based on call rate, relatedness, gender mismatch and non-Caucasian ancestry. A sample of 7358 participants remained following quality control procedures.

Imputation. Prephasing and imputation to the 1000 Genome Phase 3 reference panel (Altshuler et al., 2015) was performed using the Sanger Imputation Service (McCarthy et al., 2016), EAGLE2 (v2.0.5) (Loh et al., 2016) and PBWT (Durbin, 2014) pipeline.

Curation of summary results from GWAS of cognitive and health–related traits. Summary results from 21 GWAS of cognitive function, general health status variables, chronic diseases, health behaviors, neuropsychiatric disorders, years of schooling, social deprivation and the personality traits of conscientiousness and neuroticism were collected. For each trait, we checked the samples used in the GWAS to ensure ELSA was not included. Sources of summary statistics and key references are given in the Supplementary materials and Supplementary Table S1.

Statistical Analyses

Genome-wide association analyses. SNP-based association analyses were performed using the BGENIE v1.2 analysis package (https://jmarchini.org/bgenie/). A linear SNP association model was tested which accounted for genotype uncertainty. Prior to these analyses, the health literacy phenotype was adjusted for the following covariates: age, sex and 15 genetic principal components.
**Genomic risk loci characterization using FUMA.** Genomic risk loci were defined from the SNP-based association results, using FUncational Mapping and Annotation of genetic associations (FUMA; Watanabe et al., 2017). First, independent significant SNPs were identified using the SNP2GENE function and defined as SNPs with a p-value of < 1 x 10^-5 and independent of other genome-wide suggestive SNPs at r^2 < .6. Using these independent significant SNPs, tagged SNPs were used in subsequent annotations were identified as all SNPs that had an MAF ≥ 0.0005 and were in LD of r^2 ≥ .6 with at least one of the independent significant SNPs. These tagged SNPs included those from the 1000 Genomes Phase 3 reference panel and need not have been included in the GWAS performed in the current study. Genomic risk loci that were 250 kb or closer were merged into a single locus. Lead SNPs were also identified using the independent significant SNPs and were defined as those that were independent from each other at r^2 < .1.

**Comparison to previous findings.** A look-up of the independent significant and tagged SNPs for health literacy in the current study was performed in previous GWAS of general cognitive ability (Davies et al., 2018) and years of schooling (Okbay et al., 2016). We identified whether significant SNPs and tagged SNPs reported here reached either genome-wide (p < 5 x 10^-8) or suggestive (p < 1 x 10^-5) significance in these previous GWAS.

**Gene-based analysis implemented in FUMA.** Gene-based association analyses were conducted using MAGMA (Multi-marker Analysis of GenoMic Annotation; de Leeuw et al., 2015). The test carried out using MAGMA, as implemented in FUMA, was the default SNP-wise test using the mean p-value statistic derived on a per gene basis. SNPs were mapped to genes based on genomic location. All SNPs that were located within the gene body were used to derive a p-value describing the association found with health literacy. The SNP-wise model from MAGMA was used and the NCBI build 37 was used to determine the location and boundaries of 18,199 autosomal genes. LD within and between each gene was gauged using the 1000 genomes Phase 3 release. A Bonferroni correction was applied to control for multiple testing across 18,199 genes; the genome-wise significance threshold was p < 2.75 x 10^-6.

**Functional annotation implemented in FUMA.** The independent significant SNPs and those in LD with the independent significant SNPs were annotated for functional consequences on gene functions using ANNOVAR (Wang et al., 2010) and the Ensembl genes build 85. Functionally annotated SNPs were then mapped to genes based on physical position on the genome and chromatin interaction mapping (all tissues). Intergenic SNPs were mapped to the two closest upstream and downstream genes, which can result in their being assigned to multiple genes.

**Gene-set analysis implemented in FUMA.** In order to test whether the polygenic signal measured in the GWAS clustered in specific biological pathways, a competitive gene-set analysis was performed. Gene-set analysis was conducted in MAGMA (de Leeuw et al., 2015) using competitive testing, which examines whether genes within the gene-set are more strongly associated with health literacy than other genes. A total of 10,675 gene-sets, sourced from Gene Ontology (Ashburner et al., 2000), Reactome (Fabregat et al., 2016) and SigDB (Subramanian et al., 2005) were examined for enrichment of health literacy. A Bonferroni correction (p < .05/10,675 = 4.68 x 10^-6) was applied to control for the multiple tests performed.

**Gene-property analysis implemented in FUMA.** A gene-property analysis was conducted using MAGMA in order to indicate the role of particular tissue types that influence differences in health literacy. The goal of this analysis was to test if, in 30 broad tissue types and 53 specific tissues, tissue-specific differential expression levels were predictive of the association of a gene with health literacy. Tissue types were taken from the GTEx v6 RNA-seq database (Ardlie et al., 2015) with expression values being log2 transformed with a pseudocount of 1 after winsorising at 50, with the average expression value being taken from each tissue. Multiple testing was controlled for using a Bonferroni correction (p < .05/53 = 9.43 x 10^-4).

**Estimation of SNP-based heritability.** The proportion of variance explained by all common SNPs was estimated using univariate genome-wide complex trait analysis (GCTA-GREML; Yang et al., 2010). The sample size for the GCTA-GREML is slightly smaller than that used in the association analysis (n = 5661), because one individual was excluded from any pair of individuals who had an estimated coefficient of relatedness of >.025 to ensure that effects due to shared environment were not included. The same covariates were included in the GCTA-GREML as for the SNP-based association analysis.

**Polygenic profile analyses.** Polygenic profile scores were created using PRSice version 2 (Euesden et al., 2015; https://github.com/choisingwan/PRSice). First, we used the GWAS results for health literacy to create health literacy polygenic profile scores in an independent sample and used these scores to predict health literacy, cognitive function and educational attainment phenotypes. Polygenic profile scores for health literacy were created in 1005 genotyped participants from the Lothian Birth Cohort 1936 (LBC1936) study (Deary et al., 2007) by calculating the sum of alleles associated with health literacy across many genetic loci, weighted by the effect size for each loci. Before the polygenic scores were created, SNPs with a MAF of <.01 were removed and clumping was used to obtain SNPs in LD (r^2 < .25 within a 250 kb window). Five scores were then created that included SNPs according to the significance of the association with health literacy, based on the following p-value thresholds: p < .01, p < .05, p < .1, p < .5 all SNPs. Linear regression was used to investigate whether polygenic profiles for health literacy were associated with performance on the Newest Vital Sign (Weiss, 2003) or the ADD QoL (https://www.isa.org.uk/quality-of-life). Models were adjusted for age, sex and four genetic principal components, and standardized betas were calculated.

Next, we used summary GWAS results from 21 GWAS of cognitive and health-related phenotypes to create polygenic profile scores for cognitive and health-related traits in ELSA participants. As the creation of polygenic scores requires summary GWAS results from an independent sample, the GWAS of general cognitive ability (Davies et al., 2018) was rerun removing ELSA participants. SNPs with a MAF of < .01 were removed and clumping was used to obtain SNPs in LD (r^2 < .25 within a 250 kb window) prior to the creation of the polygenic scores. Five scores were created for each phenotype based on the p-value thresholds detailed above. For Alzheimer’s disease, we created a second set of scores with a 500 kb region around...
the APOE locus removed [hereafter called ‘Alzheimer’s disease (500 kb)’] to create a polygenic risk score of Alzheimer’s disease with and without the APOE locus.

These polygenic scores were converted to z scores. Logistic regression was used to investigate whether polygenic profiles for cognitive and health-related traits were associated with having adequate, compared to limited, health literacy in ELSA participants. All models were adjusted for age at wave 2, sex and the 15 genetic principal components to control for population stratification. For each phenotype, five logistic regression models were run using the five polygenic scores created based on the $p$-value thresholds; thus, a total of $(5 \times 21) = 105$ models were run. To control for multiple testing, the reported $p$-values are false discovery rate-corrected. This method controls for the number of false positive results in those that reach significance (Benjamini & Hochberg, 1995). A multivariate logistic regression model was run including all of the significant polygenic scores, controlling for age, sex and 15 genetic principal components to test whether these polygenic scores independently contributed to health literacy.

Results

Of the 7358 participants who remained following genotyping quality control procedures, 5783 (3160 female; 54.6%) had completed the health literacy test at wave 2 and form the analytic sample (mean age = 65.49, SD = 9.55). A total of 4012 (69.4%) participants had adequate health literacy, whereas 1771 (30.6%) participants had limited health literacy. Participants with limited health literacy were older (mean age = 67.76, SD = 10.00) than participants with adequate health literacy (mean age = 64.72, SD = 9.19; $t(3140.90) = 10.91$, $p < .001$).

Genome-wide association study. A genome-wide association analysis of health literacy found no genome-wide significant ($p < 5 \times 10^{-8}$) SNP associations. There were 131 suggestive SNP associations ($p < 1 \times 10^{-5}$). The SNP-based Manhattan plot is shown in Figure 1 (the SNP-based QQ plot is shown in Supplementary Figure S1; suggestive SNPs are reported in Supplementary Data S1). Genomic risk loci characterization performed using FUMA with the genome-wide suggestive significance threshold ($p < 1 \times 10^{-5}$) identified 39 ‘independent’ significant SNPs distributed within 36 loci; see Methods section for the description of independent SNP selection criteria. Details of functional annotation of these independent suggestively significant SNPs and tagged SNPs within the 36 loci can be found in Supplementary Data S2.

Comparison with previous findings. Of the 39 independent suggestively significant and 253 tagged SNPs (those in LD with the independent suggestively significant SNPs), none had been reported as reaching genome-wide ($p < 5 \times 10^{-8}$) or suggestive ($p < 1 \times 10^{-5}$) significance in previous GWAS of general cognitive ability or years of education.

Gene-based analyses. No genome-wide significant findings were found from the gene-based association analysis; the gene-based association results are shown in Supplementary Data S3 (the gene-based Manhattan plot is shown in Figure 1; the QQ plot is shown in Supplementary Figure S1). The gene-set and gene-
property analyses also did not identify any significant results (Supplementary Data S4 and S5).

**SNP-based heritability.** We estimated the proportion of variance explained by all common SNPs to be 0.085 (SE = 0.072). We note that, with the large standard error, this does not rule out zero SNP-based heritability.

We did not calculate genetic correlations between health literacy and those phenotypes included in the polygenic profile analyses as we did not have adequate power in this sample to utilize either the LD score regression method or, for those phenotypes also available in ELSA, bivariate GCTA-GREML. The mean chi-squared value for the health literacy phenotype was 1.009, which is below the LD score regression recommended threshold of 1.02 (Bulik-Sullivan et al., 2015). This indicates that there is too small a polygenic signal for these methods to work with.

**Health literacy polygenic profile scores predicting health literacy, cognitive function and educational attainment in LBC1936.** Polygenic profile score for health literacy did not significantly predict performance on the Newest Vital Sign, cognitive ability or years of schooling in LBC1936 (Supplementary Table S2).

**Cognitive and health-related polygenic scores predicting health literacy in ELSA.** Table 1 shows the results of the association between cognitive and health-related polygenic scores and health literacy in ELSA participants, using the most predictive threshold. Supplementary Table S3 reports the full results for all thresholds.

Increased odds of having adequate, compared to limited, health literacy were associated with a one standard deviation higher polygenic profile score for general cognitive ability [OR = 1.34, 95% CI (1.26, 1.42)], verbal-numerical reasoning [OR = 1.30, 95% CI (1.23 -1.39)] and years of schooling [OR = 1.29, 95% CI (1.21, 1.36)]. Reaction time and childhood IQ polygenic scores did not predict health literacy. Decreased odds of having adequate health literacy were associated with a 1 standard deviation higher polygenic profile score for poorer self-rated health [OR = 0.92, 95% CI (0.87, 0.98)] and schizophrenia [OR = 0.91, 95% CI (0.85, 0.96)]. No other polygenic scores predicted health literacy.

To examine whether each polygenic profile score improved the prediction of health literacy, the Nagelkerke pseudo $R^2$ value for a model with only the covariates (age, sex and 15 genetic principal components) was subtracted from the Nagelkerke pseudo $R^2$ for the model with both covariates and the polygenic score (Table 1). Polygenic profile scores for general cognitive ability, verbal-numerical reasoning and years of schooling accounted for 2.2%, 1.8% and 1.7%, respectively, of the variance in health literacy. The variance in health literacy accounted for by the self-reported health and schizophrenia polygenic scores was small, at 0.2% and 0.3%, respectively.

Table 2 shows the results of the multivariate logistic regression in which polygenic scores for general cognitive ability, verbal-numerical reasoning, years of schooling, self-rated health and schizophrenia were all entered simultaneously. The odds ratios for all polygenic scores were attenuated in this model. Increased odds of having adequate, compared to limited, health literacy were significantly associated with the following: higher polygenic scores for general cognitive ability [OR = 1.18, 95% CI (1.06, 1.32)] and years of schooling [OR = 1.19, 95% CI (1.11, 1.27)]; and lower polygenic risk for schizophrenia [OR = 0.93, 95% CI (0.88, 0.99)]. Together, these polygenic profile scores accounted for 3.0% of the variance in health literacy. In this multivariate model, the association between the verbal-numerical reasoning polygenic profile score and health literacy was attenuated and nonsignificant. This is not surprising as the general cognitive ability polygenic score is derived from a metaanalysis, which includes the verbal-numerical reasoning test (Davies et al., 2018). The self-rated health polygenic score was also attenuated and nonsignificant in this model.

**Discussion**

Using a sample of 5783 middle-aged and older adults living in England, no SNPs were found to be significantly associated with health literacy; however, we report 131 suggestive SNP associations within 36 independent genomic loci. Using polygenic profile scoring, this study found that genetic variants previously associated with higher general cognitive ability, verbal-numerical reasoning and more years of schooling were associated with having adequate health literacy, whereas genetic variants previously found to be associated with poorer self-rated health and a diagnosis of schizophrenia were associated with having limited health literacy. These results suggest that the phenotypic associations frequently reported between health literacy and cognitive function, and health literacy and health might be partly due to shared genetic etiology. In a multivariate model in which all the significant polygenic scores were entered simultaneously, higher polygenic scores for general cognitive ability, years of schooling and schizophrenia remained significant, suggesting these polygenic scores independently contribute to performance on a health literacy test.

A number of studies have reported phenotypic associations between performance on tests of health literacy and cognitive function (Boyle et al., 2013; Möttus et al., 2014; Murray et al., 2011; Reeve & Basalik, 2014). Due to the strength of these reported associations, some researchers (Möttus et al., 2014; Reeve & Basalik, 2014) have proposed that health literacy and cognitive function are not separate constructs and are instead assessing to a substantial extent the same underlying ability. To investigate this overlap, Reeve and Basalik (2014) entered three health literacy tests and six cognitive tests into an exploratory factor analysis. No unique health literacy factor emerged, and in fact, the three health literacy tests each loaded on different factors (Reeve & Basalik, 2014). The authors concluded that there is very little evidence that health literacy is unique from cognitive function (Reeve & Basalik, 2014). The current study found that the genetic variants associated with cognitive function make significant contributions to performance on tests of health literacy, providing additional evidence that health literacy and cognitive function are intrinsically related and that they might, in part, be associated with the same underlying construct.

Some researchers have suggested that educational attainment can be used as a proxy for cognitive ability in genetic studies (Hill, Marioni et al., 2019; Okbay et al., 2016) because: (a) there are large phenotypic and genetic correlations between cognitive function and educational attainment (Hagenaars et al., 2016) and (b) it is much easier to collect information on educational attainment than it is to administer cognitive assessments in large studies. In the current study, when all significant polygenic scores were entered simultaneously, the general cognitive ability polygenic score and the years of schooling polygenic score both had independent associations with health literacy. Thus, at least when measuring health literacy, it might not be appropriate to consider cognitive function and educational attainment
polygenic scores as proxies for the same underlying ability. On the other hand, it is possible that educational attainment was indexing some aspects of cognitive function not tapped by the phenotypes that went into the cognitive GWAS, which tended to be more fluid in characterization.

The results of the current study provide some evidence that the frequently reported associations between health literacy and health (Berkman et al., 2011) might be partly due to shared genetic influences. We found that genetic variants associated with poorer self-reported health and having a diagnosis of schizophrenia were associated with having poorer health literacy. Many studies have reported phenotypic associations between health literacy and self-reported health status (Berkman et al., 2011; von Wagner et al., 2007; Wolf et al., 2005). There has been relatively little research investigating health literacy and schizophrenia; however, health literacy has been found to be negatively associated with other mental health outcomes including mental health status (Wolf et al., 2005) and depressive symptoms (Gazmararian et al., 2000). The ELSA sample used here consisted of relatively healthy community-dwelling adults. In this sample of participants without schizophrenia, having a higher polygenic risk of schizophrenia was associated with poorer health literacy. This mimics the results seen for schizophrenia and cognitive function. Individuals with higher polygenic risk of schizophrenia tend to perform more poorly on tests of cognitive function (Hagenaars et al., 2016; McIntosh et al., 2013). In this study, whereas the association between polygenic risk of schizophrenia and poorer health literacy was attenuated when also controlling for cognitive polygenic scores, polygenic risk of schizophrenia remained a

Note: FEV1 = forced expiratory volume in 1 s; BMI = body mass index. The associations between the polygenic profile with the largest effect size (threshold) and the health literacy phenotype are reported.

*Nagelkerke Pseudo R^2. R^2 is calculated by subtracting the value of a model containing only the covariates (age, sex and 15 genetic principal components) from the model including the polygenic profile score and covariates.

†p-values reported have been FDR-adjusted. FDR-adjusted significant p-values are shown in bold.
significant predictor of health literacy, suggesting the associations reported here are not simply because of any overlap between cognitive function and schizophrenia.

One strength of the current study is that we used GWAS summary results from a large number of cognitive and health-related traits, which enabled a comprehensive investigation of the shared genetic influences between health literacy, cognitive function and health. Whereas phenotypic associations between health literacy and health-related traits such as type 2 diabetes (Wolf et al., 2005) and Alzheimer’s disease (Kaup et al., 2014; Yu et al., 2017) have been identified, we did not find that genetic variants previously associated with these health-related traits were associated with health literacy in this study. One limitation of the current study is that the quality of the polygenic profile scores created depends on the quality of the original GWAS. Many of the GWAS are meta-analyses, which introduces heterogeneity in both the genetic methods used and in measuring the phenotype. Some of the GWAS have relatively small sample sizes. It is possible that we did not find an association between some of the health and cognitive polygenic scores with health literacy because the original GWAS was underpowered to identify genetic associations with the phenotype.

Unlike recent GWAS of cognitive function (Davies et al., 2018; Savage et al., 2018), which found many genetic variants associated with cognitive function, we found no SNPs significantly associated with health literacy. It is now well known that for polygenic traits, the effect of individual genetic variants on a trait is likely to be very small and therefore larger sample sizes than the one used here are required to identify such associations (Deary et al., 2019). Identification of many genetic variants associated with cognitive function is only now possible because of the ever-increasing sample sizes. For cognitive function, early studies of approximately 3500 individuals found no significant SNPs (Davies et al., 2011). However, a more recent GWAS of cognitive function used data from over 300,000 individuals and found over 1000 significant SNPs (Davies et al., 2018). The GWAS reported here is therefore underpowered. Given the cognitive literature, much larger samples sizes — at least 10 times larger — than the sample size used here are probably needed to begin to understand the specific genetic variants involved in health literacy. There are, however, few large studies that measure health literacy. The present study is the first investigation of the molecular genetic contributions to health literacy. We encourage other groups with both health literacy and genetic data to explore the genetic associations of health literacy. In an effort to increase power, future studies should look to conduct a metaanalysis of GWAS of health literacy.

None of the suggestively significant SNPs identified in this study have previously been reported as genome-wide significantly associated with cognitive function (Davies et al., 2018) or years of schooling (Okbay et al., 2016). If health literacy, cognitive ability and education do have shared genetic influences, and the suggestive health literacy findings reported here are found to be true associations, then they appear to be associated with an aspect of health literacy that does not have shared genetic etiology with cognitive function or years of education. However, given the small sample size, some of the observed suggestive signals reported here may be due to chance.

The present study found that the SNP-based heritability for health literacy was 8.5% (SE = 7.2%), which is lower than has been reported in studies testing the SNP-based heritability of cognitive phenotypes (Davies et al., 2011, 2018). The heritability estimates for cognitive function were calculated using much larger samples than were used here. For example, the SNP-based heritability for general cognitive function was found to be 25% (SE = 0.6%) using a sample of 86,010 UK Biobank participants (Davies et al., 2018). Measurement characteristics of health literacy in the present study probably lowered the estimate of SNP-based heritability. In common with other studies using this test (Gale et al., 2015; Kobayashi et al., 2014), we dichotomized test scores into adequate (4/4 correct) and limited (<4 correct) health literacy. Given the brief nature of this test, and given that we have defined health literacy as a dichotomy, it is possible that the SNP-based heritability estimate reported here was attenuated. Longer tests, which can capture the continuum in health literacy variance, would be preferable and could test this possibility. On the other hand, we note that dichotomous variables in this general area can result in larger SNP-based heritability; for example, having or not having a college or university degree in the UK Biobank sample had a SNP-based heritability of 21% (SE = 0.6%; Davies et al., 2016).

One strength of this study is that health literacy was measured consistently in all participants. One limitation is that the health literacy measure used in ELSA is a brief, four-item test that has a ceiling effect. That is, 70% of participants scored full marks (4/4) on this test. Despite the brief nature of the ELSA health literacy test, and despite the ceiling effect, this measure has been found to be associated with various health outcomes, including mortality (Bostock & Steptoe, 2012). In the current study, this health literacy test was sensitive enough to identify associations with polygenic scores for cognitive and health-related traits. Future research examining the genetic contributions to health literacy should use more detailed and continuous measures of health literacy.

Phenotypic associations have consistently been found between health literacy — the skills and ability required to manage one’s health — and cognitive function and health. This study is the first to investigate whether health literacy and cognitive function, and health literacy and health, share genetic architecture. In this study we investigated the genetic associations of health literacy and tested whether genetic contributions to cognitive function and health are associated with health literacy. No SNPs had genome-wide significant associations with health literacy. Polygenic scores for cognitive function, years of schooling, self-reported health and schizophrenia were significantly associated with performance on a brief test of health literacy. These results indicate that the phenotypic associations between health literacy and cognitive function, and health literacy and health may be partly due to shared genetic etiology between these traits. Future studies should build on the heritability estimate and polygenic profile results reported here and explore the genetic overlap and distinctiveness of health literacy, cognitive ability, education.

Table 2. Multivariate models of the association between polygenic profiles of cognitive and health traits with having adequate health literacy, controlling for age, sex and 15 genetic principal components

Note: ORs and 95% CIs are from a model in which all five polygenic scores are entered simultaneously, controlling for age, sex and 15 genetic principal components. *p-values reported have been FDR-adjusted (after a false discovery rate correction across five tests). FDR-adjusted significant p-values are shown in bold.

and health. As the number of participants increases, we will be able to determine the SNPs, genes, and gene-sets that are shared and distinct between health literacy, cognitive function and health.
